The Evolution of Transit Access to Jobs in American Cities

Sierra Arnold*

Draft: November 2, 2026

Abstract

Households without a car are largely limited to the jobs they can reach by public transportation. We measure job access by transit as the jobs reachable within 45 minutes on the scheduled transit network. No consistent sub-annual series of this measure has existed for U.S. cities. We construct a quarterly neighborhood panel for 52 metropolitan areas over 2014–2025, routed from archived schedules with one fixed method. Access depends on the transit schedule, the number of jobs, and where they are, and we separate the three. The typical neighborhood's job access by transit rose about 15%, falling below its 2014 level in 2020 and ending above its pre-pandemic peak. In metros with clean archives, job growth alone would have produced more than the entire rise. The schedule's own contribution was roughly nothing before 2020 and negative after, a level we bound against agency-reported service data, and jobs relocating toward transit-served places offset most of that loss. The growth went to richer, car-owning, peripheral neighborhoods, while the poorest quartile gained essentially nothing and majority-Black neighborhoods lost longer-reach access outright once archive entries are removed (−13% within 60 minutes), in the handful of metros where their population concentrates. Within cities, at the same distance from the same core, growth accrued to richer neighborhoods, overwhelmingly through where employment located. Weighted by car-free households, the rise is +2.5%, against +15% for the average resident. The paper is descriptive; we make no causal claims about employment.

Keywords: Job accessibility; public transit; GTFS archives; spatial mismatch; transport equity

Routing was performed on resources provided by the Ohio Supercomputer Center (Ohio Supercomputer Center, 1987), whose support we gratefully acknowledge.

1 Introduction

About 8% of U.S. households have no vehicle available (U.S. Census Bureau, 2023). Not driving is more common among lower-income and Black adults. In a 2024 survey, 19% of lower-income adults and 21% of Black adults said they rarely or never drive, compared with 3% of upper-income adults and 7% of White adults (Pew Research Center, 2024). For workers in these households, the jobs they can reach by transit make up much of the set of jobs they can take. Research on spatial mismatch has long linked access to jobs with employment for workers without cars.

Transit agencies decide where and how often buses and trains run, and they revise their schedules several times a year. They report the service they operate and the trips riders take to the National Transit Database. Neither number shows how many jobs residents can reach. Regional transportation plans now commonly list access to jobs among their goals, but few plans measure it. Federal civil rights guidance also requires large agencies to test whether major service changes fall disproportionately on minority and low-income populations. Each of these tasks depends on knowing how many jobs residents can reach by transit, and how that number changes when service changes. Section 2 reviews this research and practice.

Between 2014 and 2025, both the transit network and the location of jobs changed. In 2020 agencies cut service as ridership fell. In 22 U.S. cities, those cuts reduced transit access to food and health care most in neighborhoods with high poverty and many households without vehicles (Kar et al., 2022). Over the same decade, metropolitan areas added jobs, and the location of those jobs shifted within each metro. The number of jobs a neighborhood can reach by transit depends on the network and on the number and location of jobs. Service statistics alone therefore cannot show whether residents ended the decade able to reach more jobs by transit or fewer. This paper asks how job access by transit changed across U.S. neighborhoods from 2014 to 2025. It also asks how much of the change came from transit service and how much from jobs, and which neighborhoods gained or lost.

Prior work has established that job access by transit is low in most U.S. metropolitan areas and far below job access by car. The *Access Across America* series reports annual levels for metropolitan areas (Owen et al., 2025). The *Modal Access Gap* program maps the transit/car gap by block group (Maharjan et al., 2024). The Transit Equity Dashboard tracks block-group access in seven regions from 2020 onward (Klumpenhouwer et al., 2021), and a recent study follows New York City block groups across four snapshots (Zhang et al., 2026). None of these sources measures neighborhood job access by transit across many metropolitan areas, more often than once a year, with one method held fixed for a decade. Without such a series, a change in measured access cannot be distinguished from a change

in method or data. The parts of a change that are due to the transit network and to the location of jobs also cannot be separated.

We construct a quarterly panel of job access by transit for every census block group in 52 U.S. metropolitan areas and in New York, from 2014 to 2025. We refer to block groups as neighborhoods. For each neighborhood and quarter, we count the jobs a resident can reach within 45 minutes by transit and walking, departing in the morning peak. Travel times are computed from archived transit schedules (GTFS feeds) with one routing method held fixed across all metros and quarters. Job counts come from the Census LEHD Origin–Destination Employment Statistics. We analyze New York separately (Section 6), because its job access by transit is about ten times that of the other metros and its income and race gradients differ from theirs.

We measure change by comparing each neighborhood with itself over time. Because the schedule archive added transit operators over the decade, we do not count an operator's first appearance in the archive as new service. We then split each neighborhood's change into three parts, using the 19 metros whose schedule archives have no flagged quarters. The first holds jobs fixed and lets only the transit schedule change. The second is growth in the metro's total number of jobs, and the third is the movement of jobs within the metro. We also report the ratio of job access by car to job access by transit, which is an order of magnitude or more. Our car travel times assume free-flowing traffic, so the ratio overstates the car advantage. We report it for single years rather than as a trend, because its change over time mostly reflects the car measure. The paper is descriptive. It measures access to jobs, not employment.

We find three things. First, the typical neighborhood's job access by transit rose about 15% from 2014 to 2025, after falling below its 2014 level in 2020. Second, the rise came from jobs. Growth in the number of jobs alone would have produced more than the entire rise. The transit schedule added almost nothing before 2020 and reduced access after 2020, and jobs moving toward places served by transit offset most of that reduction. Third, the gains went mainly to higher-income, car-owning neighborhoods at the edges of metropolitan areas. Weighted by households without a car, access rose 2.5%, compared with 15% for the average resident. For practice, these results show that service statistics and job access can move in opposite directions, and that averages over all residents can overstate what car-free households gained.

The paper proceeds as follows. Section 2 reviews the related literature and planning practice. Section 3 describes the data and the construction of the panel. Section 4 defines the access measure and the methods for measuring change. Section 5 presents the results.

Section 6 reports the results for New York. Section 7 discusses the limitations and the implications for practice, and concludes.

2 Related Literature

Accessibility measures the opportunities that can be reached from a location within a given travel budget, a concept dating to Hansen (1959). Subsequent work has developed cumulative-opportunity, gravity-based, and utility-based measures and has clarified the strengths and limitations of each approach (Handy and Niemeier, 1997; Geurs and van Wee, 2004). In practice, however, cumulative-opportunity and gravity-based measures generally produce similar conclusions when calibrated to comparable travel-time thresholds (Santana Palacios and El-Geneidy, 2022), making the availability of consistent longitudinal data more consequential than the particular accessibility metric employed. Accessibility fluctuates within the day, though a constant peak-hour measure tracks relative accessibility across neighborhoods closely (Boisjoly and El-Geneidy, 2016). A further methodological thread decomposes a change in accessibility into the part attributable to the transport network and the part attributable to the population or land-use (here, job) distribution (Stepniak and Rosik, 2018; Rosik et al., 2025). A related literature separates the same two contributions across design scenarios (Lahoorpoor et al., 2022). Applying these decompositions to observed changes over time, however, requires accessibility measures computed consistently across years, which is the requirement the panel developed here is built to meet (Section 3).

While this literature establishes how accessibility is measured, the more important question for this paper is what those measures reveal about U.S. transit systems. Applied to U.S. transit, these measures have produced a body of direct evidence on how little of a metropolitan job market a rider can reach. Tomer et al. (2011) provide a 100-metro cross-section, and the *Access Across America* series (Owen et al., 2016), building on continuous-accessibility methods (Owen and Levinson, 2015), reports transit accessibility annually, with a parallel automobile series. Its recent editions report year-over-year comparisons (Owen and Murphy, 2020) and describe a decade of consistently calculated data (Owen et al., 2025). Because each edition pairs that year's schedules with that year's employment data, its year-over-year changes combine service change with economic change. The Transit Equity Dashboard (Klumpenhouwer et al., 2021) tracks block-group transit access and its demographic incidence in seven large U.S. regions from February 2020 forward. Closest to our object is the *Modal Access Gap* program: transit versus car job access computed at the block-group level across the largest U.S. metropolitan areas, with an explicit focus on carless and underserved populations (Maharjan et al., 2024). The same group measures transit against walking in

the 50 largest metros, reading the gap as an effectiveness indicator (Ermagun and Witlox, 2024). This work establishes the cross-sectional gap and its spatial structure, including the finding that carless households tend to live where the gap is narrower (Maharjan et al., 2024); its temporal dimension is travel time rather than calendar time (Janatabadi et al., 2023). Consequently, existing studies can describe where transit accessibility is high or low, but they cannot distinguish how observed changes over time reflect changes in transit networks versus changes in the spatial distribution of employment.

What gives these magnitudes their economic weight is the spatial mismatch hypothesis (Kain, 1968), which holds that physical disconnection from employment depresses labor-market outcomes for disadvantaged workers. The hypothesis and its mechanisms have been reviewed extensively (Ihlanfeldt and Sjoquist, 1998; Gobillon et al., 2007). A strand of this work stresses that mismatch is as much modal as spatial, because a worker without a car faces a far smaller opportunity set than a driver from the same location (Grengs, 2010). Studies of transit itself find that better access to public transit is associated with higher labor-force participation in Portland and Atlanta (Sanchez, 1999). When damage from Hurricane Sandy reduced subway service to parts of New York, unemployment rose in the affected neighborhoods, most among residents who depend on transit (Tyndall, 2017). A systematic review of 93 studies finds a positive association between transport and employment. The association is clearest for car ownership, and the evidence for public transit is thinner (Bastiaanssen et al., 2020). Kain's hypothesis also has a job side. Employment in U.S. metros has decentralized for decades (Glaeser and Kahn, 2001), with job share shifting away from the urban core in nearly every large metro through the 2000s (Kneebone, 2009). Kain identified that movement as a cause of the mismatch. Whether decentralization has been pulling jobs toward or away from the places transit serves is an empirical question about the joint evolution of the two, and answering it requires observing both over calendar time.

How access is distributed across people and places has been studied on both empirical and normative grounds; the normative case is reviewed by Pereira et al. (2017). Foth et al. (2013) track transit access against neighborhood social need in Toronto across two census years, and Yeganeh et al. (2018) compare access by income and race across U.S. metropolitan areas in a single cross-section. Most closely, Zhang et al. (2026) track block-group transit access to jobs and services across four snapshots for New York City, decomposing a widening racial access gap into transit-network and residential-sorting components. The measurement is made feasible by general-purpose routing over open schedule data (GTFS) and street networks (Conway et al., 2018; Pereira et al., 2021). The closest precedent reconstructs a retrospective timetable from vehicle-location data (Wessel et al., 2017). The pandemic's fall

in transit demand is documented across U.S. systems (Liu et al., 2020), an episode within the decade our panel covers rather than its subject.

Accessibility also has a growing place in planning practice. A review of 32 metropolitan transportation plans from North America, Europe, Australia and Asia finds that most include accessibility among their goals, most often as access to jobs, but few use accessibility-based indicators to guide decisions (Boisjoly and El-Geneidy, 2017). A content analysis of 42 U.S. regional transportation plans finds that most include accessibility-related goals, but few define the term or use accessibility-oriented performance measures (Proffitt et al., 2019). Equity objectives in North American plans are often stated without measures that can assess their achievement for different population groups (Manaugh et al., 2015). For transit service, federal civil rights guidance requires agencies that operate 50 or more fixed-route vehicles in peak service, in urbanized areas of 200,000 or more people, to conduct service equity analyses of major service changes (Federal Transit Administration, 2012). The outcome of such an analysis can depend on whether it uses census or onboard-survey data (Karner and Golub, 2015). Agencies report the service they operate and the trips riders take to the National Transit Database each month (Federal Transit Administration, 2026). In 2020, agencies cut frequencies in many areas and raised them in others, and the cuts appear to have fallen disproportionately on lower-income and more vulnerable areas of 40 North American cities (DeWeese et al., 2020).

Taken together, these literatures establish the level of U.S. job access by transit, the cross-sectional shape of its modal gap, its distribution at a point in time, and its use as a planning goal, and they supply the machinery for decomposing a change in access. The object that remains open is job access by transit observed in calendar time: at the block group, on a single method held fixed, at sub-annual resolution, across many metros. That is the panel this paper builds, and it draws on each of these literatures in turn. We adopt the transparent cumulative measure, carrying gravity and logsum variants as robustness, and allocate every change between the network and the jobs with a reference-period-invariant Shapley decomposition (Shorrocks, 2013). *Access Across America* serves as a validation benchmark and the National Transit Database as an independent check on the network component (Appendix A). The modal gap enters as a secondary, cross-sectional upper bound, and the strict-contemporaneity and service-calendar rules of Section 3.2 meet the archived-feed fidelity issues directly.

3 Data

We assemble a neighborhood-level panel of transit and car job access for 52 U.S. metropolitan areas outside New York, plus New York itself, measured quarterly from 2014 through 2025. It combines four sources: an archive of transit schedules, the location of jobs, the street network, and demographic context. Assembling consistently routable schedules at sub-annual resolution, on harmonized dates across more than a decade, has not been done before.

3.1 Data sources

Transit service is described by General Transit Feed Specification (GTFS) feeds. GTFS defines a common format for public transportation schedules and the geographic information that accompanies them. An agency publishes its routes, its trips, the location of every stop, and the time a vehicle is scheduled to serve each one. The specification exists so that this data can be consumed by software, which is what puts transit directions into applications like Google Maps, and nearly every transit agency in the country adheres to it. There is, however, no national repository of feeds. Each agency keeps its own schedules, and superseded versions are ordinarily discarded, so a feed downloaded today describes only today's service. What makes a historical panel possible is that community archives capture dated snapshots and keep them. We assemble ours from two such archives, Transitland and the Mobility Database, supplemented by SEPTA's own published archive for Philadelphia's recent years.

Job locations come from the Census LEHD Origin–Destination Employment Statistics (LODES) Workplace Area Characteristics, which report job counts at the workplace Census block annually; we aggregate them to the block group, so that both ends of a trip are measured on the same geography. We route from block-group origins and count jobs at block-group destinations. We count all jobs throughout; LODES also separates jobs by earnings band, but its low-wage band is a fixed nominal threshold that holds fewer jobs each year as wages grow, so no low-wage access measure is reported. Version 8 of LODES reports every year on 2020 census blocks, so the destination geography is stable across the panel. Because the jobs data are annual, sub-annual movement within any year is driven entirely by changes in the transit schedules.

Door-to-door routing uses the OpenStreetMap (OSM) street and path network. This maps the walk-ride-walk time for transit, and the drive time for cars. The car alternative is free-flow using posted speeds with no congestion, parking, or access-and-egress penalty, which overstates real driving access and hence the size of the gap. The gap's level is thus

Table 1: Descriptive statistics, 52-metro balanced panel outside New York

	Mean	SD	p10	p50	p90
A. Job access (block group × quarter)					
Transit jobs ≤ 45 min	44,214	115,756	276	6,768	107,221
Car jobs ≤ 45 min	1,536,484	1,204,558	237,127	1,181,697	3,163,993
Transit/car ratio R	0.034	0.120	0.0005	0.0058	0.100
B. Neighborhood characteristics (block group)					
Population	1,500	800	686	1,374	2,455
Median household income ($000)	96.7	49.1	43.5	86.8	164.4
Below 200% poverty (%)	27.0	20.4	4.8	22.0	57.2
Zero-vehicle households (%)	7.7	11.7	0.0	3.2	21.9
Non-Hispanic White (%)	52.1	30.7	6.0	56.5	90.8
Non-Hispanic Black (%)	12.9	21.8	0.0	3.2	42.1
Hispanic (%)	23.0	25.5	0.2	12.9	65.1
Non-Hispanic Asian (%)	7.3	12.1	0.0	2.3	21.4
Distance to urban core (km)	7.2	11.0	0.6	3.4	18.3

Note: Panel A is pooled over block-group × metro × quarter (flagged cells excluded), 45-minute budget, all jobs; R is the transit/car ratio, an upper bound (Section 4.1). Panel B is per block group ($n \approx 85{,}700$), from ACS 2018–2022. New York excluded.

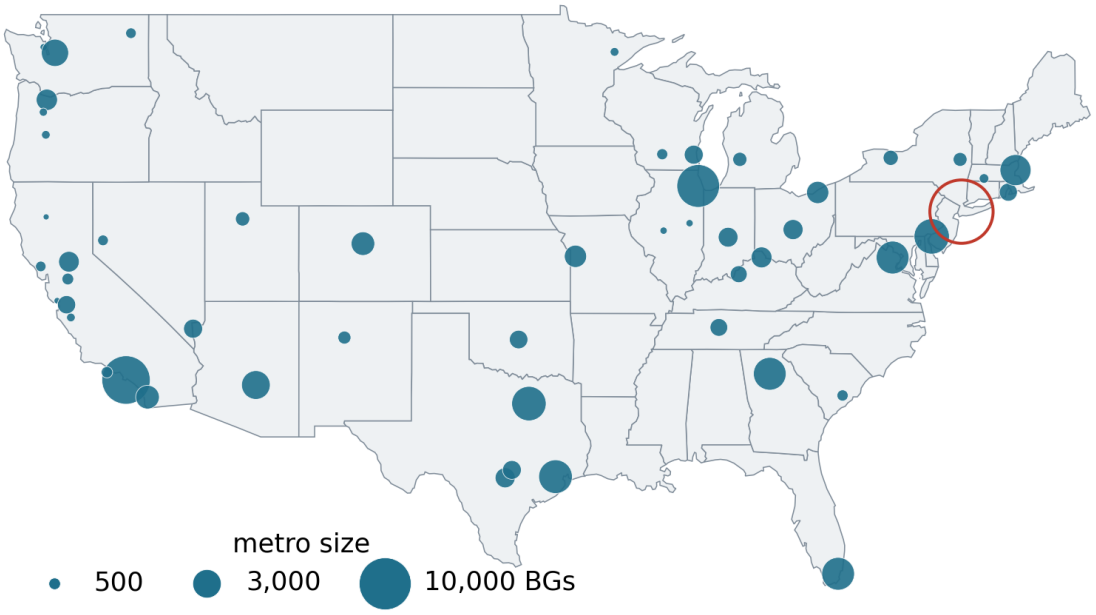

best read as an upper bound on the car advantage. A present-day OSM extract is used, so the car baseline reflects today's roads. The quarterly trajectory is driven by the transit series.

Neighborhood income, race, and vehicle availability come from the American Community Survey, used both to characterize who has car access and to identify transit-reliant neighborhoods (high zero-vehicle households and high below-poverty shares). This is a neighborhood-level intersection rather than a household-level one. The block group is the unit throughout; 2020 block-group population centroids anchor each neighborhood's origin for routing. Table 1 reports descriptive statistics for the access measures and the neighborhood characteristics.

3.2 Panel construction

For each operator serving a metro we take the feed in effect on the second Wednesday of January, April, July, and October of each year (a representative mid-week, mid-quarter service day), combine all the operators that serve the metro into a single routable network, and route that schedule. A metro-quarter is thus the service that was actually operating on that date. Seasonal timing does not drive annual comparisons. Quarter-of-year effects are small, each quarter sitting within about a log-point of its year's mean, so the choice of the second Wednesday does not affect the results.

Figure 1: The 52 panel metropolitan areas outside New York

Note: The 52 U.S. metropolitan areas outside New York analyzed at quarterly resolution, 2014–2025; point area is proportional to the number of block groups. New York, analyzed separately in Section 6, is the hollow marker. Anchorage, also in the panel, lies outside the map.

Agencies republish their feeds at every service change, several times a year in the recent era, and these versions are archived, so sub-annual sampling resolves service changes, above all the COVID-19 collapse and recovery, that an annual snapshot would miss. This sub-annual depth is feasible only in the recent era; routed quarters exist back to 2013, but the archive there is thin, so the analysis window, and every exhibit, runs 2014–2025. We also do not substitute feeds across dates. A metro-quarter includes an operator only when its feed is strictly contemporaneous, meaning its service period spans the sample date; an operator without one is dropped from that quarter rather than backfilled with a stale feed. Dropping rather than imputing keeps stale service out of the panel. Where an operator drops out between quarters in which it is present, the cell would understate access, and the partial-outage flag removes it from value figures.

Coverage in the archive is uneven (sparse in the early years, densest in 2016–2019, and thinner through a 2020–2023 trough), so the analysis uses a near-balanced panel: the 52 metropolitan areas outside New York (Fig. 1) present in at least 36 of the 48 quarters of 2014–2025. The trend is then not contaminated by metros entering and leaving the sample. We refer to it as the balanced panel for brevity; per-metro coverage is in Appendix A. New York is set aside as a separate case, because its extraordinary transit supply both dominates any population-weighted average and inverts gradients found elsewhere. This panel is the

sample every level, trajectory, and distributional exhibit uses, narrowed to the metros where both endpoint windows are observed (45 of 52) only when an exhibit needs a decade change; the decomposition alone uses a stricter cut, the clean-archive core, defined in Section 5.1. Table A.2 lists each exhibit's sample.

3.3 Data quality and representativeness

An operator whose feeds were never archived in the early years is invisible to quality scans, which detect changes rather than absences; this archive adoption is removed by the trajectory's archive-entry correction (Section 4.2) rather than left to contaminate the trend. Feeds that are archived can still misrepresent the service actually running; we flag the affected metro-quarters rather than dropping them, and flagged cells are excluded from all value figures while still counting as present for coverage (Appendix Table A.3 lists the classes, detection rules, and counts). Because internal scans cannot catch everything, the archive is also corroborated against agency-reported service, which flagged cells every internal check had passed (Appendix A). Finally, GTFS encodes scheduled rather than delivered service (Section 7).

The panel over-represents larger, transit-intensive metropolitan areas, because inclusion depends on historical GTFS availability rather than random sampling. The 52 cover about 45% of total U.S. metropolitan population, including 30 of the 50 largest metros and 40 of the largest hundred, and are more transit-oriented, though no more car-free, than the typical metro. They miss several of the largest legacy systems whose archives do not span the window: San Francisco–Oakland, Minneapolis–St. Paul, Detroit, and Baltimore. Washington is included, but its WMATA feed is unarchived, so its access is understated throughout. The omissions plausibly bias the trajectory in one direction. The legacy systems that are in the panel are its decliners (Section 5.6), so the absent ones, large, old, and cutting service after 2020, would more likely pull the trajectory down than up. The full panel-versus-nation profile, per-metro coverage, and the named omissions are in Appendix A (Tables A.1, A.4). We read the results as describing job access by transit in the covered metros rather than in the average U.S. metro.

4 Measuring Transit Access to Jobs

4.1 The accessibility measure

The unit of the panel is the block group × metro × quarter. For each metro-quarter we build a routable network from the metro's OpenStreetMap extract and the operators' strictly-contemporaneous GTFS feeds and compute door-to-door travel times between every pair of block-group population centroids.

Travel times are computed with R5 (Conway et al., 2018). For transit we take the median door-to-door time over departures in the 7:00–9:00 morning peak, so that a value reflects typical rather than best-case timing and does not depend on a single departure time. Trips longer than 90 minutes are treated as out of reach, well beyond the 45-minute primary budget. Walking uses the engine's default speed with no separate distance cap, and all other routing parameters are the engine defaults, held fixed across every metro and quarter. Because routing runs centroid to centroid, travel times are coarsened in large peripheral block groups; the centroids are fixed, so this measurement error is time-invariant and nets out of the within-neighborhood trajectory. Car travel times come from the same engine on the same street network, so the two modes differ only in how a traveler moves. From the resulting travel-time matrix we form cumulative access: the count of jobs at destinations reachable within a fixed time budget. The cumulative job access by transit of origin block group i in metro-quarter q at budget τ is

$$A_{i,q}^{(\tau)} \;=\; \sum_{j} \text{jobs}_{j,y(q)} \cdot \mathbf{1}\Big[\, t_{ij}^{\text{transit}}(q) \le \tau \,\Big], \qquad \tau \in \{15, 30, 45, 60\} \text{ min},$$

where $t_{ij}^{\text{transit}}(q)$ is the transit travel time on the schedule operating in quarter q and $\text{jobs}_{j,y(q)}$ is jobs at destination j in the annual LODES vintage $y(q)$ of that quarter; car access $A_{i,q}^{(\tau),\text{car}}$ is identical but for car travel times on the fixed street network. The transit/car ratio $R_{i,q} = A_{i,q}^{(\tau),\text{transit}} \big/ A_{i,q}^{(\tau),\text{car}}$ at the same origin ($R = 0.01$ is a hundredfold car advantage) enters only as a secondary comparison, reported with the levels in Section 5.3. Because the car baseline is free-flow, the car advantage this ratio implies is an upper bound. We do not follow the ratio over time, because its movement is dominated by the car denominator and by sprawl rather than by transit.

We report the 45-minute budget as primary; we count all jobs (LODES C000) throughout (Section 3.1 explains why no low-wage band is reported). Cumulative access is the most transparent and most widely reported construct. Two alternatives drop the hard cutoff: gravity measures, which count every job but discount it smoothly by travel time (here a negative exponential with a 45-minute half-life), and utility-based (logsum) measures, which

Figure 2: Job access by transit per block group: Cincinnati, 2023Q4

Note: Jobs reachable within 45 minutes by transit, per block group, Cincinnati 2023Q4 (log scale, central 30 km). Every panel cell is one such map, per metro per quarter.

summarize the expected value of choosing among all reachable destinations. Once scaled to a common budget, both are about 0.9 correlated with cumulative access in our data (Table A.6, Appendix A), as Santana Palacios and El-Geneidy (2022) find for gravity measures, so we carry them as robustness. Access climbs steeply with the time budget, roughly forty-five-fold between 15 and 60 minutes (Table A.5), but the overall series at each budget move in parallel across the decade, so the shape of the trajectory does not depend on the 45-minute choice. The group comparisons in Section 5.4 vary in size with the budget.

The primary object is job access by transit itself. Figure 2 maps it for one mid-size panel metro. Access peaks downtown and falls by roughly two orders of magnitude toward the periphery. We summarize it population-weighted (the access of the average person, the convention in the cumulative-opportunity literature, Owen and Levinson, 2015) and report the median block group, the typical neighborhood, as a companion. Access is sharply

right-skewed within a metro, near zero across the low-service periphery and high in the service-bearing core; in the metro mapped here the median block group reaches about 5,400 jobs.

We check the measure against two external sources. Across the 390 metro-years that overlap the published *Access Across America* series, our metro levels agree with theirs at log correlations of 0.88–0.95. Our levels sit at a stable fraction of the published values, about 0.6, because our metropolitan areas include a low-access periphery that the series' urban areas leave out and because the two series weight neighborhoods differently (Fig. A.5). The measure also predicts behavior. Metros with more jobs reachable by transit have more workers who commute by transit ($r = 0.77$ outside New York; Fig. A.6).

4.2 Measuring change

The trajectory is the change in job access by transit in each quarter relative to the 2014 annual average. It compares each block group only with itself, so the large differences in access between neighborhoods do not move it when some metros are missing from a quarter. Formally, it is the set of quarter coefficients from a population-weighted regression of log access on quarter indicators and block-group fixed effects.

The archive also grew over the decade. In every panel metro, at least one operator's schedules first appear in the archive after the metro's first year. Counted directly, each such entry would appear as new transit service. The archive-entry correction therefore counts change only between quarters with the same set of archived operators. In the quarter an operator enters, the jump in access is not counted as growth, and the comparison continues from the new level. This is the splice familiar from chained price indices, which link an index across a change in its basket of goods. In the regression, the block-group fixed effect becomes one fixed effect for each block group and each period over which its metro's set of archived operators is unchanged.

The correction drops no observations. Every quarter stays in the panel, and only the step at an operator's entry is left out of the trend. The correction is conservative, because an operator that began running when it entered the archive is left out of the trend as well. We checked the larger entries against agency-reported service where that was possible. Each was the archive beginning to collect an existing operator's feed, except in Columbus, where the entry is new service. Treating the five cases in which an operator leaves the archive as real service changes moves the 2025 estimate by less than a tenth of a log-point. Figure A.1 shows the uncorrected and corrected series for Miami. Across the panel, the uncorrected index ends

2025 at about +22 log-points (+25%), against +14 for the corrected index (Fig. A.2). The difference of about eight log-points is archive adoption rather than service.

4.3 The decomposition

The decomposition separates each block group's change in log access into a network part and a jobs part. Conceptually, we ask what access would have looked like if only transit had changed, and separately if only jobs had changed. Holding the 2014 job map fixed and letting only the network change isolates the network's own contribution; holding the 2014 network fixed and letting only jobs move isolates the job side. Measured this way, the two parts do not quite add up to the observed change, because the network and the job map also changed together. We therefore average each part over both choices of which year is held fixed, 2014 or the later year, and the averaged parts sum exactly to the observed change in every block group. The split into transport and land-use parts follows the decomposition literature (Rosik et al., 2025), and the averaging is the symmetric allocation of the Shapley construction (Shorrocks, 2013). The jobs part splits exactly in two. Metro-wide job growth is the growth of the metro's job total, because growth in the same proportion everywhere raises every block group's access by that proportion. Job relocation is the remainder, employment shifting toward or away from the places transit serves. The decomposition is annual, because LODES reports jobs once a year, and its components are measured against the 2014 annual average, because the archive's early quarters are thin.

Confidence intervals throughout are clustered at the block group, which absorbs the serial correlation of a neighborhood with itself over time. By the design-based logic of Abadie et al. (2023) this is the right uncertainty for describing the panel we observe, since we hold essentially the entire population of its block groups. For claims that read as a common process across metros, we also report metro-clustered intervals (Table A.7) and scope the text to whichever the evidence supports.

5 The Evolution of Job Access by Transit

Unless noted, results are on the panel, the balanced 52 metros outside New York (Section 3.2), population-weighted, at the 45-minute budget for all jobs; the decomposition alone uses the stricter clean-archive core. Trajectories compare each block group with itself and are corrected for archive entry (Section 4.2), and confidence bands are clustered at the block group. New York, an order of magnitude more transit-rich and with several gradients in the opposite direction, is analyzed separately in Section 6. Section 5.1 decomposes the rise,

and Section 5.2 shows the full trajectory. Sections 5.3 to 5.5 cover the distribution within cities, asking who has access, who gained it, and how car-free households fared. Section 5.6 compares metros, and Section 5.7 covers the pandemic.

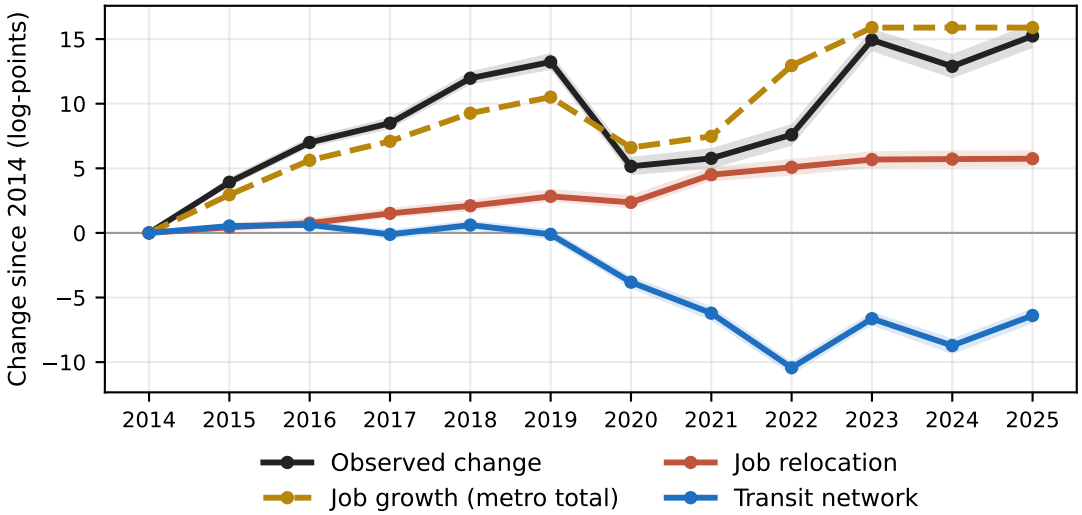

5.1 What drove the rise: network or jobs?

Over 2014–2025 the typical neighborhood's job access by transit rose about 15%. The more informative question is what drove that rise. Did job access by transit improve because the network expanded, or because the jobs moved toward it? The decomposition of Section 4.3 separates the two.

The answer is the paper's central finding (Fig. 3). The decomposition is estimated on the clean-archive core: of the panel's 52 metros, the 35 whose block groups are observed unflagged in every year, and among those the 19 with no flagged quarter at all across the decade (28,147 block groups; membership in Table A.2). Metros with flagged eras are excluded whole, because their component paths track changes in archive quality rather than in service. Their measured networks appear to improve during the pandemic. The exclusion protects the component paths. The 2025 endpoints change by only a fraction of a log-point without it, and the jobs-side components are nearly identical on the full every-year sample (Fig. A.4). Measured against the 2014 annual average, and in the log-point units in which the components add, metro job growth alone would have added +15.9 log-points to the typical neighborhood's job access by transit as of 2025. The transit network's own contribution holds within a point of zero through 2019 and then falls sharply after the pandemic, ending at −6.4 log-points. This is the documented post-2020 service reduction, measured as a component of access rather than as service hours. Job relocation contributes +5.7 log-points. Employment moved toward transit-served locations, offsetting most of the network's negative contribution. Where that relocation occurs resolves an apparent tension with the results in Section 5.4. By distance to the core, the relocation component is slightly negative in the two inner quartiles (about −1 log-point) and strongly positive at the fringe (+16), concentrated in fast-growing metros. Employment moving outward leaves the set of jobs reachable from the core and enters the sets reachable from mid-ring and peripheral neighborhoods. Summed over all neighborhoods, this outward movement counts as relocation toward transit-served places. The three sum exactly to the observed +15.2 log-points, a rise of about 16.4%, on this sample. The 52-metro trajectory puts the decade at +14.1 log-points (+15.1%); Table A.8 reconciles the two. The largest of its three steps is the sample itself, because the clean-archive metros grew faster. That step moves the observed rise, not the split. The endpoint check, which moves the 2025 components by a fraction of a log-point,

holds the sample fixed and varies the flag treatment. Metro job growth and job relocation survive clustering at the metro level, and so does the net decade change (Appendix A). They are common processes across the 52 metros. The transit network component, by contrast, has a metro-clustered interval that spans zero; metros' network paths genuinely diverge (Section 5.6). Neighborhoods reach more jobs by transit than in 2014 because employment grew, not because transit improved. Jobs are observed through 2023, so 2024–25 movement is network-only by construction; a decomposition ending at 2023 reads nearly identically ($+14.9 = +15.9 + 5.7 - 6.6$).

Figure 3: Network, job-growth, and job-relocation components of the change in job access by transit, 2014–2025

Note: Decomposition of the change in job access by transit into the transit network (jobs held at 2014), metro-wide job growth, and job relocation components, within block group, annual, population-weighted, the clean-archive core (19 metros outside New York), indexed to the 2014 annual average; vertical axis in log-points, the units in which the three components sum to the observed change. Shading is the 95% block-group-bootstrap band.

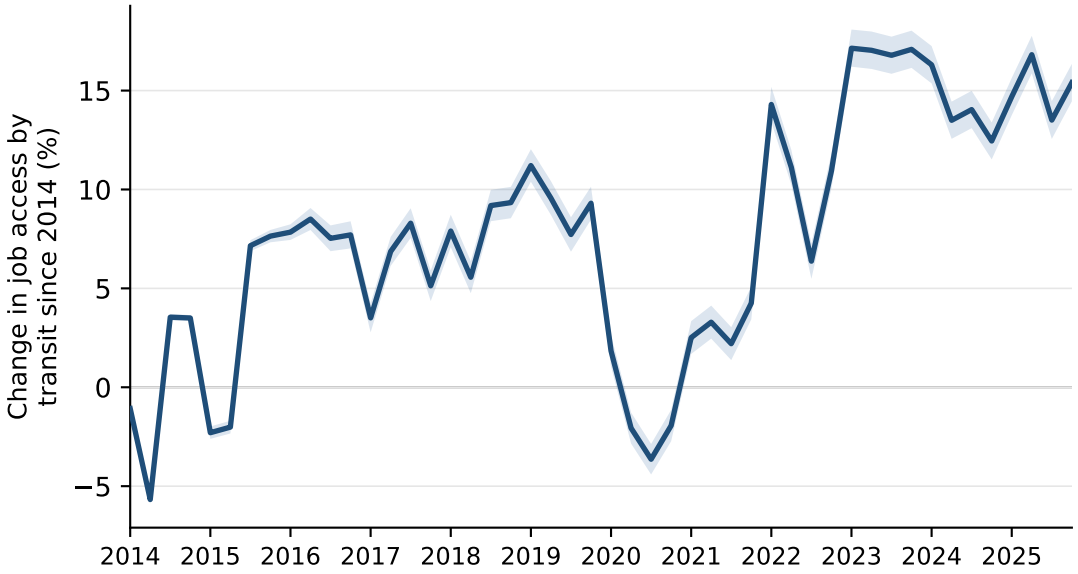

5.2 The trajectory, in full

Figure 4 shows the full quarterly trajectory on the 52-metro panel. The typical neighborhood's job access by transit rose about +9% by late 2019 (+8.9 log-points [8.1, 9.7]) and fell below its 2014 level during 2020 (−3.7 [−4.5, −2.9] in 2020Q3). It recovered to about +15% by 2025 (+14.1 log-points [13.3, 14.8]; +15.1% in ratio terms), above its pre-pandemic peak. These intervals describe the panel; as a statement about a common national process the net decade change holds up, with a metro-clustered interval excluding zero (about [+6, +24]; Appendix A), though metros vary widely around it, the dispersion Section 5.6 documents.

The sub-annual panel resolves the COVID-19 collapse and recovery at the neighborhood level, which an annual series cannot.

The raw population-weighted level, by contrast, is an unreliable guide to how access moved. Depending on how neighborhoods are weighted, which metros are present in each period, and whether flagged cells are included (Sections 3.3 and 5.6), it ranges from modestly positive to slightly negative over the decade. Including flagged cells, the corrected index ends at +17.7% rather than +15.1%; Appendix Table A.3 lists the flag classes, their detection rules, and the cells each caught.

Figure 4: Change in job access by transit relative to 2014, quarterly, 2014–2025

Note: Within-block-group fixed-effects change in jobs reachable within 45 minutes by transit, corrected for archive entry, relative to the 2014 average, population-weighted, balanced 52-metro panel outside New York. Shading is the 95% block-group-clustered band.

5.3 Within cities: who has job access by transit?

The panel's neighborhood resolution makes the within-city distribution of access, and of its change, a main subject of the paper. An area-aggregated series cannot measure this distribution, and a single cross-section cannot measure its change.

The transit/car gap is large. Outside New York the population-weighted average neighborhood reaches roughly thirty-eight-fold fewer jobs by transit than by car within 45 minutes; for the median neighborhood the shortfall is about 172×; by time budget the gap runs 86× at 15 minutes and eases, without closing, to about twentyfold within an hour (Appendix A).

The two summaries differ because access is severely right-skewed. The ratio of population-weighted means is pulled toward the transit-rich core, where transit does comparatively well, while the median neighborhood's own ratio is far larger. The statement in Section 1 that the gap is an order of magnitude or more refers to the smaller, mean-based figure.

Levels and growth give opposite answers, and we take them in turn. In levels (as of 2023), job access by transit is highest in the neighborhoods that rely on it. Population-weighted on the balanced panel, the poorest within-metro income quartile reaches about 1.9× the access of the richest; neighborhoods where more than a third of households are car-free reach about 14× the access of car-owning ones; high-poverty neighborhoods reach about 2.4× low-poverty ones; and central neighborhoods reach roughly 50× the urban fringe. Outside New York, majority-Black neighborhoods reach more than majority-White ones (about 2.1×), while majority-Hispanic neighborhoods reach about the same (1.0×). Each ratio's confidence interval excludes one, except the Hispanic contrast, whose interval includes one, so access is about the same in majority-Hispanic and majority-White neighborhoods (Table 2). A natural objection is that these gradients merely restate urban form, because poor, car-free, and minority households live centrally, where transit is. Controlling for distance to the urban core separates the two. The car-reliance gradient survives within every distance band. Car-free neighborhoods reach more jobs by transit than their car-owning neighbors at the same distance from the center. The income and poverty gradients also survive within every band, strongest in the 5–30 km suburban ring and attenuated but still pro-poor in the dense core. The racial gradient, by contrast, is near one within distance bands. The majority-Black advantage in the pooled comparison reflects where those neighborhoods sit (closer to the core) rather than race per se.

Table 2: Job access by transit across neighborhood groups

Group contrast (G1 / G4)	G1	G4	Ratio	95% CI
Income: poorest / richest	53.4	28.0	1.90	[1.77, 2.05]
Car-free: >30% / <10%	240.1	16.9	14.21	[13.54, 14.92]
Poverty: >60% / <20%	72.2	29.7	2.43	[2.28, 2.59]
Distance: core / fringe	124.0	2.4	50.75	[48.70, 52.89]
%Black: >60% / <10%	71.5	33.6	2.13	[1.99, 2.28]
%Hispanic: >60% / <10%	37.0	37.9	0.98	[0.92, 1.04]

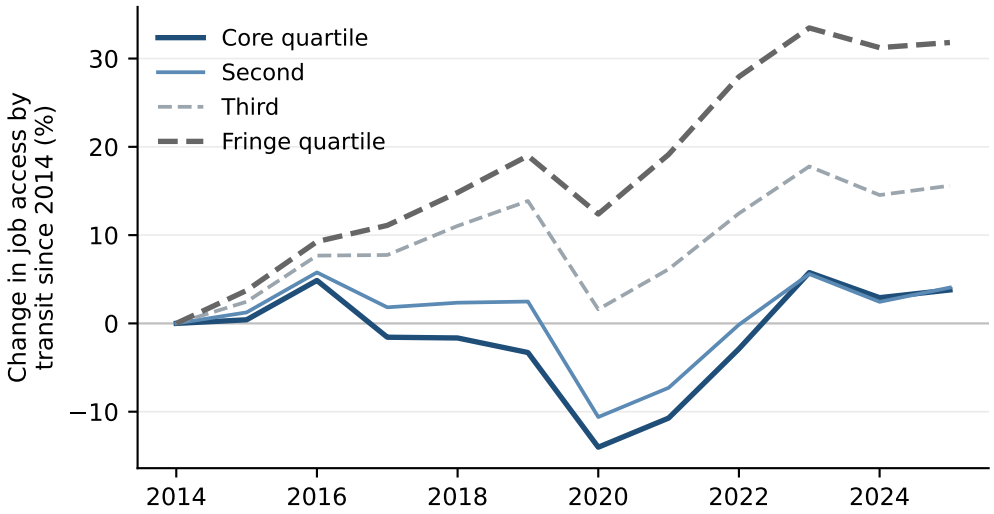

Note: 45-minute budget, 2023, 52 metros outside New York, in thousands of jobs. Group 1 and Group 4 access (population-weighted means of block-group 2023 values, thousands) and their ratio with a delta-method 95% confidence interval, all jobs (C000); each row is the more transit-reliant group over its reference group, so a ratio above one favors the reliant group (ratios computed before rounding).

5.4 Within cities: who gained access?

Growth ran in the opposite direction from levels, and on the corrected index the difference is large (Fig. 5). The urban fringe gained about 32% over the decade while the core gained little (+4%), and this distance gradient appears in every demographic comparison (Fig. 6). The richest income quartile gained about 31% while the poorest gained essentially nothing (−0.3%); the most car-owning neighborhoods gained about 19% while the most car-free gained essentially nothing; low-poverty neighborhoods gained about 22% while high-poverty neighborhoods gained barely a point. The largest difference is by race. Majority-White neighborhoods gained about 16% (majority-Hispanic about 11%), while majority-Black neighborhoods' job access by transit declined, by about 9% within 45 minutes and by roughly 13% within 60 minutes. The decline is concentrated in the handful of metros where most residents of majority-Black neighborhoods live. The within-city gaps opened before the pandemic. In the distance-controlled comparison of Table 3, the poorest–richest contrast had already reached roughly −20 log-points by 2019, most of its decade value. The gradient is not an artifact of the 45-minute budget. It holds at every threshold, steeper at 30 minutes (the richest quartile gained about +40% against the poorest's +5%) and shallower at 60 (about +26% against −2%). The majority-Black decline grows with the budget. Longer-reach access, which covers more of the metro's jobs, fell the most. The uncorrected data hide this decline. The operators that entered the archive after 2014 disproportionately serve poorer and majority-Black neighborhoods, so archive adoption masked their losses. Because majority-Black population weight is concentrated in those few metros, the decline is a fact about them rather than an estimate of a uniform national process (its metro-clustered interval spans zero; Appendix A); the gains in richer, whiter, peripheral neighborhoods, by contrast, are metro-robust. The mechanism is the one the decomposition identifies (Section 5.1). The movement is chiefly on the jobs side, with reachable-job counts growing where jobs grew and falling where they declined (Table 3). In percentage terms low-access peripheral neighborhoods converged toward high-access central ones; in absolute terms every change is small against the level differences (the fringe's +32% is under a thousand reachable jobs; the core's few-percent gain, several thousand). We report both readings and attach no welfare claim to either.

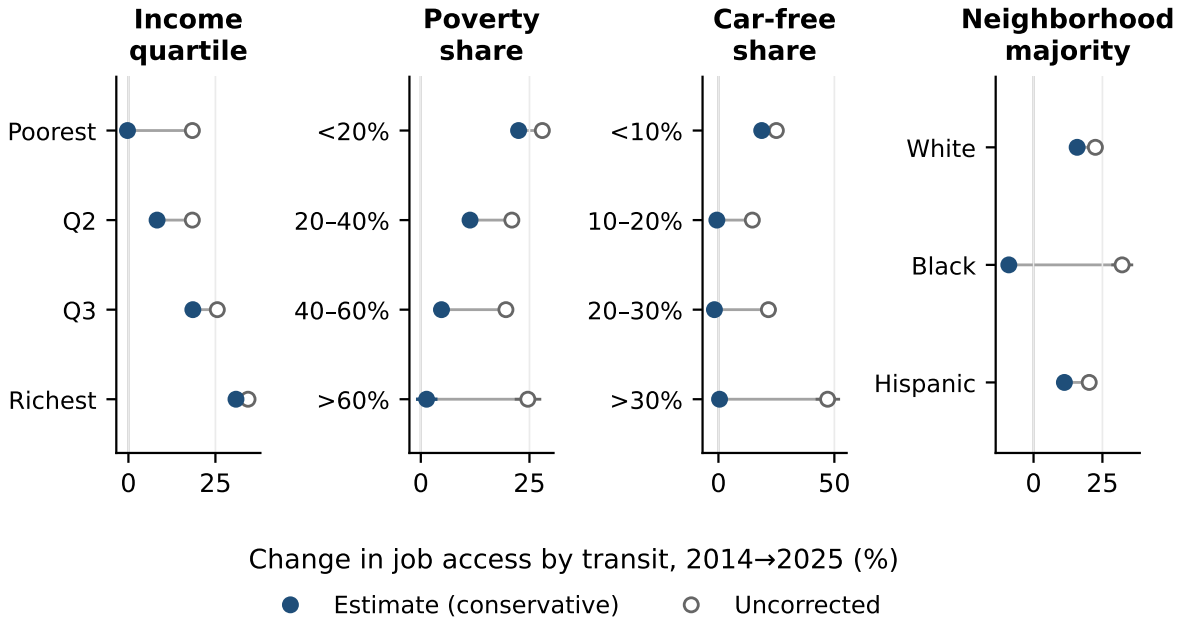

The growth gradient is not a composition of growing metros, nor of urban form alone. Comparing each neighborhood only to others in the same metro and the same five-kilometer distance band (Table 3), the income gradient survives essentially intact. The poorest quartile's access grew 20.7 log-points less than the richest quartile's over the decade (95% CI $[-22.1, -19.2]$; metro-clustered $[-26.8, -14.5]$, robust at either level). The poverty gradient is similar. The racial gap attenuates by about two-thirds, location explaining most of it,

Figure 5: Change in job access by transit across distance-to-core quartiles, 2014–2025

Note: Within-block-group change in job access by transit relative to 2014, by distance-to-core quartile, annual, population-weighted, 52 metros outside New York, flagged cells excluded.

Figure 6: Decade change in job access by transit across neighborhood groups

Note: Change in job access by transit, 2014 to 2025, by neighborhood group. Filled markers: the estimate (conservative); open markers: the uncorrected value; whiskers are 95% block-group-clustered intervals. The distance between the two is the archive-adoption correction.

but a majority-Black shortfall of about 11 log-points remains ($[-13.0, -8.3]$; under metro clustering it spans zero, Appendix A). Decomposing each contrast into its network and jobs components, with the archive-entry correction applied equally to the observed change and

Table 3: Within-city growth incidence, distance-controlled

Contrast (within metro × distance band)	Observed	Network	Jobs
Poorest vs. richest income quartile	−20.7	−2.5	−18.8
	[−22.1, −19.2]	[−3.5, −1.5]	[−19.9, −17.7]
High- vs. low-poverty (>60% vs. <20%)	−17.9	−3.8	−15.4
	[−19.9, −15.9]	[−5.4, −2.2]	[−16.8, −14.1]
Majority-Black vs. majority-White	−10.7	−7.0	−5.1
	[−13.0, −8.3]	[−8.9, −5.0]	[−6.7, −3.4]
Car-free vs. car-owning (>30% vs. <10%)	−5.7	−0.5	−5.8
	[−7.6, −3.8]	[−2.4, +1.3]	[−6.7, −5.0]

Note: Decade change in job access by transit across neighborhood contrasts, decomposed into network and jobs components, in log-points ×100. Each cell is the coefficient on the listed group contrast from a regression of the block group's decade change (2014–15 to 2024–25 window means, in logs, corrected for archive entry: each block group's jumps at operator entries are removed) on group indicators, absorbing metro × 5-km-distance-band cells, population-weighted, robust standard errors (95% CIs in brackets); 70,057 block groups, the panel where both endpoint windows are observed (45 of 52 metros). Network and jobs columns use the per-block-group components of Section 5.1's decomposition construction, computed for this table's own sample, with the archive-entry jump removal applied equally to Observed and Network (the jobs component is adoption-free by construction), so rows approximately add; the small residual is the decomposition's ordinary approximation error. The majority-Black network entry is the corrected-basis estimate. Because each contrast differences within metro, metro-wide job growth cancels from the Jobs column.

the network part so the columns approximately add, identifies the mechanism. For income, poverty, and car-reliance the gradient is on the jobs side, with jobs-side losses of −19, −15, and −6 log-points against network components within a few points of zero. The racial contrast splits. About half is on the jobs side (−5.1 log-points, adoption-free by construction), while the sign of the network part cannot be determined (it is −7 log-points if every archive entry is treated as adoption and +7 if every entry is genuine new service), so we do not interpret it. Within the same city and the same distance from the core, employment relocated toward richer neighborhoods over the decade; for the poorest-versus-richest contrast, transit service change played essentially no role. Because neighborhoods are classified at a fixed 2018–2022 vintage, this reads as "the places that are affluent today gained access"; whether jobs moved toward richer neighborhoods or richer households moved toward access is a sorting question this comparison does not resolve. One version of the concern we can address is end-of-period sorting. Classifying neighborhoods instead by their income at the start of the period, from the 2009–13 ACS crosswalked to 2020 block groups (Schroeder et al., 2026), leaves the gradient essentially intact. The quartile richest in 2009–13 gained about +31% over the decade and the poorest about zero, the same spread as under present-day classification, and the within-city distance-controlled gap is −16 log-points (metro-clustered

$[-26, -5]$). The neighborhoods that were already better-off at the start of the period are the ones whose access grew; the pattern is not an artifact of who is rich today.

5.5 The transit-reliant margin

This section studies car-free households in low-income neighborhoods. Table 4 reports the panel for this group, using the constrained transit-reliant strata defined in Section 3.1. All statistics weight block groups by their car-free households, so each row describes the typical car-free household in that stratum. In levels, the sorting documented cross-sectionally by the Modal Access Gap literature (Maharjan et al., 2024) is visible on the constrained margin too. The typical car-free household lives where transit reaches 131,000 jobs within 45 minutes, roughly 3.5 times the population-weighted average person's 38,000 (Table A.5). Even the poorest, most car-free strata reach 130–174,000, more as the thresholds rise. Two caveats apply. Membership is fixed at the 2018–2022 ACS vintage, so the strata are today's reliant neighborhoods traced backward. Classifying them on their 2009–13 attributes instead gives the same answer (constrained endpoints of −1.2 and −0.9 percent against +3.0 for the all-neighborhood car-free line), so the small gain for car-free households is not an artifact of end-of-period sorting. The strata are also concentrated in a few dense metros (Chicago, Los Angeles, and Miami together hold about 31% of the constrained car-free weight), and New York, the most extreme case, is analyzed separately.

Table 4: Job access by transit at the transit-reliant margin

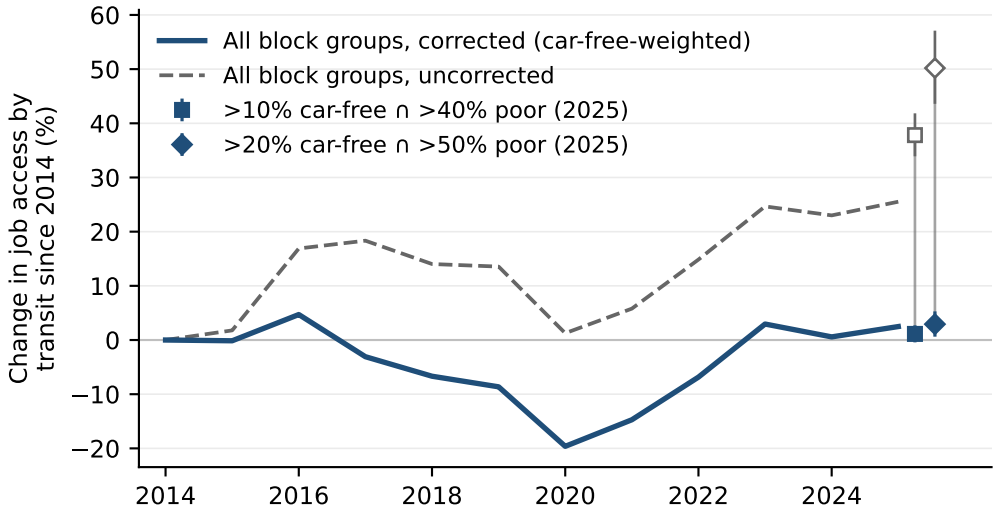

Stratum	Block groups	Car-free HH covered (%)	Access (000s)	Change 2014–25 (%)	Top-3 metro share (%)
All block groups	85,694	100	131	+2.5	29
Constrained: car-free ∩ below-200%-poverty					
>10% ∩ poor >40%	10,400	38	130	+1.1	31
>20% ∩ poor >50%	4,386	22	147	+2.9	34
>30% ∩ poor >50%	2,585	16	174	+2.8	38

Note: 52 metros outside New York, balanced panel, 2014–2025 pooled, flagged cells excluded. Access = jobs reachable within 45 minutes by transit (thousands, all jobs), weighted by car-free households (ACS 2018–2022: car-free from B25044, poverty share from C17002; membership fixed at that vintage). Change 2014–25 = the stratum's archive-entry-corrected within-block-group fixed-effects estimate for 2025 (Fig. 7). Top-3 metro share = the share of the stratum's car-free households living in its three largest metros. The reliance cut is a neighborhood-level double threshold on ACS marginals, not a household-level joint distribution (Section 7).

Over time, the decade's rise is small for this group (Fig. 7). On the index, weighted by car-free households, access for the average car-free household rose just +2.5% over the

decade (CI $[+1.6, +3.3]$), a small fraction of the +15% the average resident gained, and the constrained strata gained no more, ending between +1 and +3% above their 2014 level (block-group intervals that straddle or barely clear zero). The uncorrected series ends far higher (about +26%, Fig. 7); the gap between the two is precisely the operators entering the archive in these neighborhoods, the adoption the correction exists to remove (Section 4.2). The small gain is thus the conservative reading, and the distance-controlled comparison supports it independently. These strata start high in levels, being central, but they gained little over the decade. The more informative comparison is relative and survives the urban-form control. Comparing block groups within the same metro and the same five-kilometer distance band (the framework of Table 3), constrained neighborhoods' decade growth was 8 to 13 log-points lower than their same-distance neighbors' (metro-clustered intervals exclude zero). The shortfall is chiefly jobs-side (the jobs component alone is about 8 log-points, while the network component is small and spans zero across archive-entry treatments). It is employment relocating away from these neighborhoods rather than service withdrawal or distance to the core. This is the growth-incidence result of Section 5.4, measured for car-free households.

Figure 7: Change in job access by transit, weighted by car-free households, 2014–2025

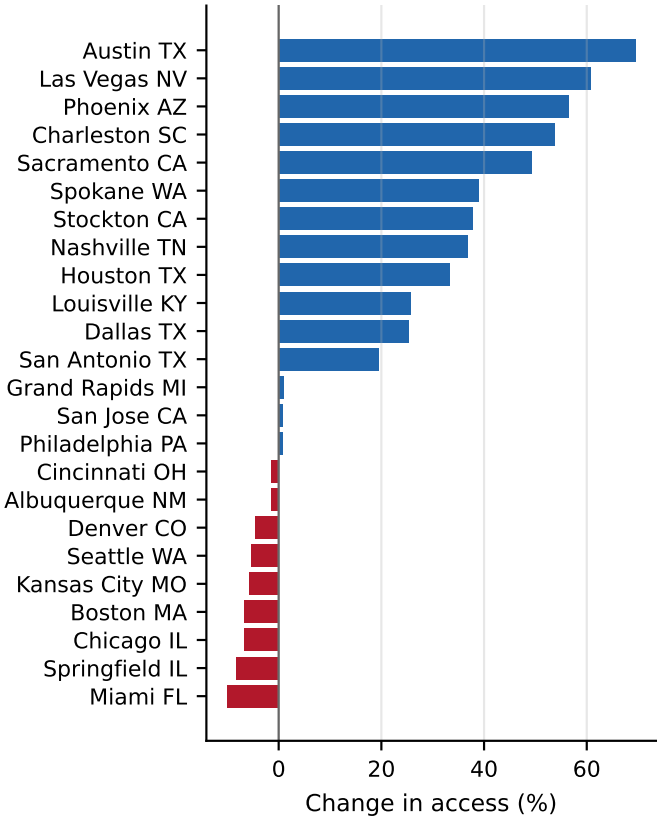

Note: Change in job access by transit relative to 2014, annual, weighted by car-free households, all block groups, 52 metros outside New York, flagged cells excluded: the corrected series (solid) and the uncorrected series (dashed); the gap between them is archive adoption. At right, the 2025 decade change for the two broadest constrained strata (>10% car-free ∩ >40% poor, squares; >20% car-free ∩ >50% poor, diamonds): filled markers corrected, open markers uncorrected, whiskers 95% block-group-clustered.

5.6 Across metros: winners and losers

The national trajectory averages over wide variation across metros, which the panel can rank because its method is held fixed (Fig. 8). The largest gains accrued to fast-growing Sun Belt and western metros (Austin, Las Vegas, Phoenix, Charleston, and Sacramento lead), while several large legacy systems lost ground: Miami, Springfield (Illinois), Chicago, Boston, and Kansas City.

Figure 8: Decade change in job access by transit across metropolitan areas

Note: The typical neighborhood's change in job access by transit, 2014–15 to 2024–25, by metro (corrected, within block group, population-weighted; top and bottom 12 of the panel where both endpoint windows are observed, 45 of 52 metros—the seven without a clean window at one or both endpoints, and hence unranked, are Bremerton, Los Angeles, Oklahoma City, Providence, Redding, Salinas, and Washington).

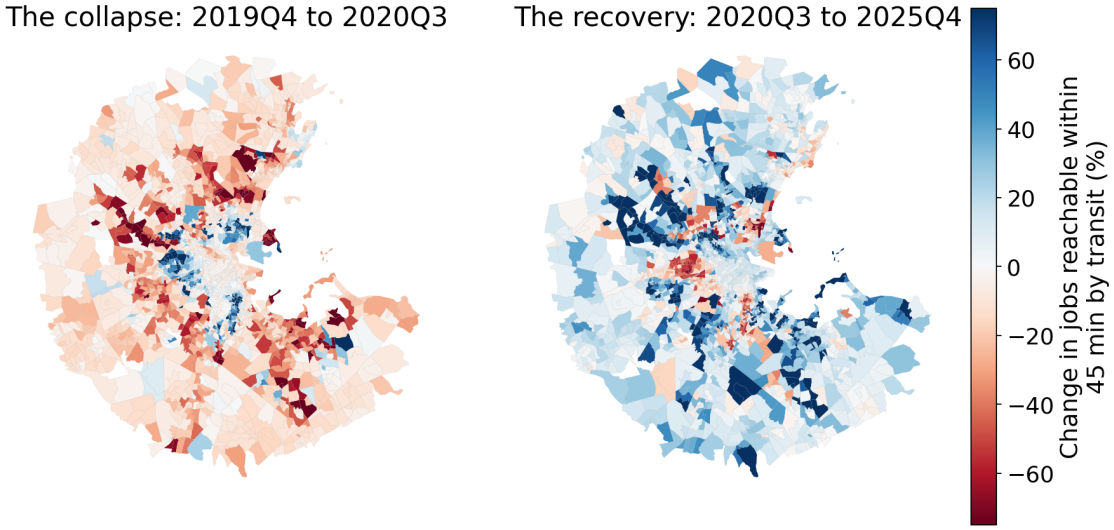

The correction matters here. On the ranking's window-mean construction, Miami's raw series shows a +18% gain that is entirely operators entering the archive after 2015. Once these entries are removed, the typical Miami neighborhood lost about 10%, the largest measurable decline (Fig. A.1 traces the same correction quarter by quarter against the 2014 mean). Chicago, whose degraded post-2020 archive we recovered from the operators' restored feeds, is now measurable too and declined about 7%, no longer the outlier its unaudited feed record

once suggested. Flagged metro-quarters are excluded throughout (Appendix Table A.3). Finding these artifacts is itself a warning that cross-metro comparisons on archived feeds require this auditing.

5.7 The pandemic, and other episodes

COVID-19 is the episode the panel resolves best. The 2020 collapse and recovery are visible in the trajectory (Fig. 4) and in the decomposition. The network component, not the jobs component, falls and fails to recover after 2020 (Fig. 3). This is the job-access counterpart of the 2020 service cuts (Kar et al., 2022). Agency-reported service data (the National Transit Database) corroborate the component's shape through the collapse and bound its incomplete recovery. All-day service miles returned faster than peak-hour job reach (Appendix A). The comparison is not circular. The core metros are never flagged by any source, the NTD scans included, so the exhibit does not select metros for agreeing with the agency data, and selection toward agreement could not produce the pre-2020 disagreement it shows. The panel adds the collapse and the recovery of job access at the neighborhood level, quarter by quarter, within the longer decade.

Figure 9: Block-group change in job access by transit, Boston, 2019Q4–2025Q4

Note: Percent change in jobs reachable within 45 minutes by transit, per block group, Boston: the collapse (2019Q4 to 2020Q3) and the recovery (2020Q3 to 2025Q4), shared diverging scale, blue for gains and red for losses (central 30 km; base $\geq$ 100 jobs). Boston is chosen for its dense, unflagged archive coverage across the display window.

Figure 9 shows the collapse and the recovery as two change maps for Boston. The collapse (left) is broad but deepest in the middle-ring neighborhoods where frequency cuts truncated marginal service; the recovery (right) reverses it, except in the neighborhoods shown in red,

where service had not returned by 2025. The mapped area's median reachable-job count fell by about a fifth (−22%) in three quarters; an annual measure would average over the entire movement. Two other episodes matter less for this panel. The 2015–19 wave of bus network redesigns aimed to reallocate service within cities, so its winners and losers can cancel in the metro mean. The post-2008 recession predates the quarterly panel and enters only as context.

6 New York: the exception

New York is not a large version of the other metros. Its access levels and gradients differ in kind, and pooling it into the primary sample would let one city dominate the national results. We therefore report it on its own; a dedicated, New-York-specific account of how its job access by transit and its racial distribution evolved is given by Zhang et al. (2026), and here we compare New York with the other metros. Four facts set it apart.

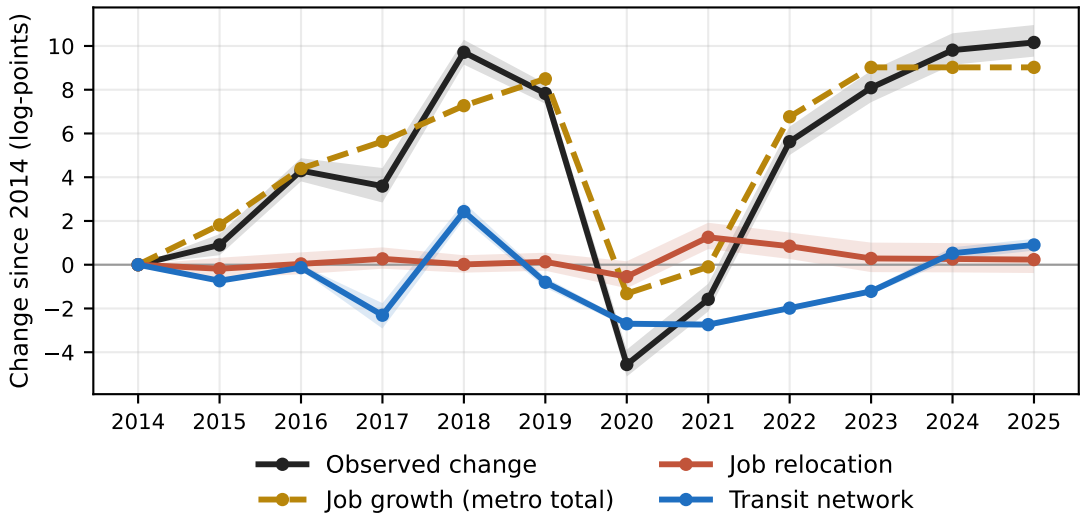

Scale. New York's neighborhoods reach about ten times the job access by transit of the typical metro elsewhere, about 396,000 jobs within 45 minutes against 38,000 outside New York (Table A.5, Appendix A). Its transit/car gap is correspondingly small, about 12× at 45 minutes against 38× elsewhere, because transit in New York is genuinely competitive with the car. By every level measure New York sits an order of magnitude apart.

Trajectory and the pandemic. Measured within block group, New York's job access by transit rose about +11% over the decade against +25% outside it, both on the uncorrected index, the like-for-like comparison, since the archive-entry correction is poorly identified for a single metro. With no cross-metro variation to separate a step at an operator's archive entry from genuine service change, New York's frequent feed reorganizations place most of its measured growth at such steps, which the correction removes (a corrected New York index sits near zero, which we read as an artifact of the construction rather than of the city). On either footing, New York rose less than the metros outside it. Its access dipped below the 2014 baseline in 2020 (about −4%), as it did outside New York. Because New York holds so large a share of national job access by transit, pooling it into a national average would pull that average down and let one city dominate it. For this reason the metros outside New York are the primary sample (Section 3.2).

The decomposition reverses. New York is the only place where the transit network's own contribution did not decline. Holding jobs fixed, its network adds about +1 log-point

over the decade, against about −6 everywhere else (Fig. 10). A likely reason is that New York's network is mature and built out, with little room to expand and, after 2020, the institutional capacity to hold service where thinner systems cut it. Its rise is almost purely job growth (about +9 log-points; net job relocation is nil at +0.2), but the decline in the network component found in the rest of the country does not occur in New York.

Figure 10: Network, job-growth, and job-relocation components of access change: New York

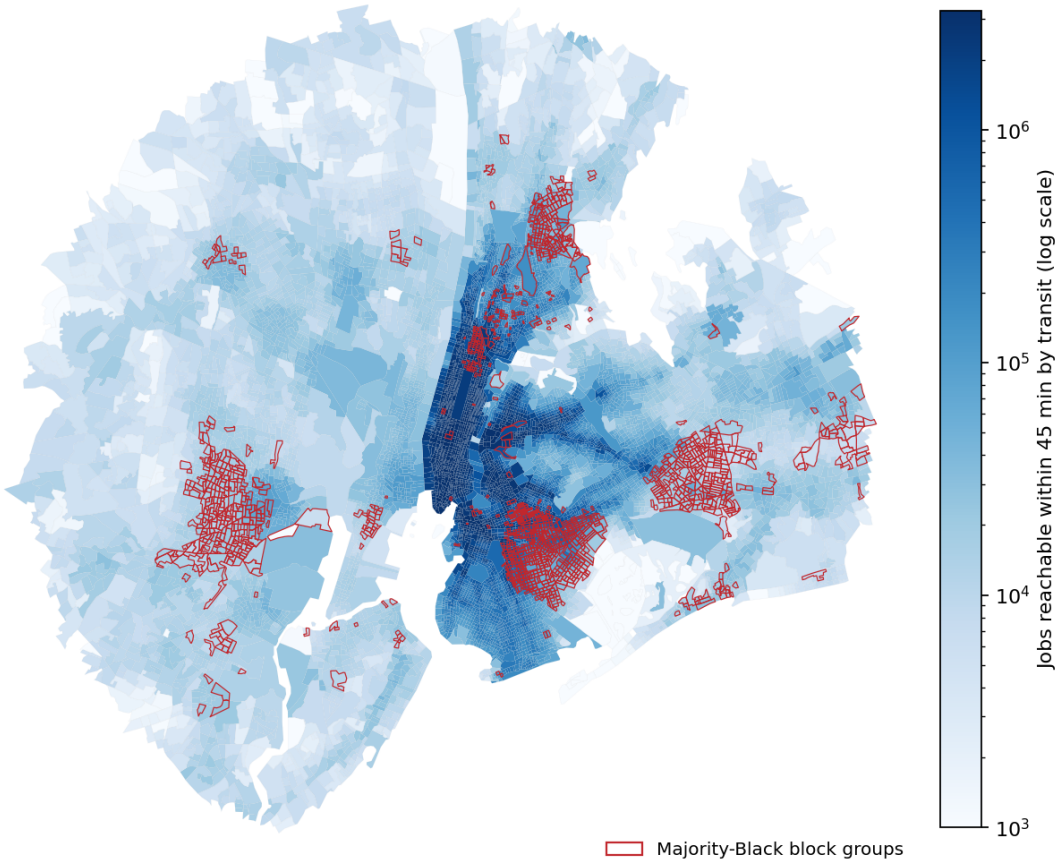

Note: The decomposition of Fig. 3 for New York alone: transit network (jobs held at 2014), job growth, and job relocation components, within block group, annual, population-weighted, log-points, indexed to the 2014 annual average.

The gradients invert. Where access elsewhere is cleanly pro-poor and pro-minority, New York's distribution runs the other way (Table 5). Figure 11 maps the racial inversion. The region's majority-Black neighborhoods sit away from the access peaks (southeast Queens, the edges of central Brooklyn, Newark) rather than on them.

The income gradient disappears. Its richest and poorest neighborhoods reach essentially the same access (1.07×, not statistically distinct), because in New York both the affluent and the poor live centrally. The racial gradient reverses. Majority-Black neighborhoods reach about a third fewer jobs than majority-White ones (0.66×), the opposite of the roughly 2.1× advantage outside New York. The reversal reflects where the city's Black neighborhoods sit, in eastern Brooklyn and the eastern Bronx, farther from the Manhattan job core. The car-reliance and distance gradients, by contrast, are even steeper than elsewhere (about 96× and 280×). Pooled into national figures, these opposing patterns would partly cancel the gradients found everywhere else, so we report New York separately.

Figure 11: Job access by transit per block group, New York, 2023Q4

Note: Jobs reachable within 45 minutes by transit, per block group, 2023Q4 (log scale, central 35 km), with the region's 1,513 majority-Black block groups outlined.

Table 5: New York: job access by transit across neighborhood groups

Group contrast (G1 / G4)	G1	G4	Ratio
Income: poorest / richest	466.7	436.7	1.07
Car-free: >30% / <10%	992.0	10.4	95.70
Poverty: >60% / <20%	579.1	319.2	1.81
Distance: core / fringe	1,283.5	4.6	279.90
%Black: >60% / <10%	259.2	393.1	0.66
%Hispanic: >60% / <10%	443.6	359.8	1.23

Note: 45-minute budget, pooled 2014–2025, in thousands of jobs; population-weighted means of block-group values, all jobs (C000). Groups are defined as in Table 2.

7 Discussion and Conclusion

Between 2014 and 2025, the typical neighborhood in the 52 metros outside New York gained about 15% in job access by transit. Access fell below its 2014 level during the 2020 service cuts and ended the period above its pre-pandemic peak. The decomposition shows where the gain came from. Growth in the number of jobs would have produced more than the entire rise. Scheduled peak-period service contributed close to nothing before 2020 and subtracted after it, and the movement of jobs toward places that transit serves offset most of that loss. The size of the network's post-2020 decline is bounded rather than precisely measured, because metros differ widely and agency-reported all-day service recovered faster than peak job reach (Appendix A). Its near-zero contribution before 2020 and its 2020 collapse are clear. The gains were not shared evenly. Access is highest in poor, central, car-free neighborhoods, but the growth went mainly to higher-income, car-owning neighborhoods at the edges of metros, where jobs grew. Weighted by car-free households, access rose 2.5%, compared with 15% for the average resident, and majority-Black neighborhoods, concentrated in a few metros, ended the decade below their 2014 access. New York is the exception. Its network held its contribution over the decade (Section 6).

These results describe how transit networks and the geography of employment interacted over the decade. The common assumption that rising access reflects transit investment does not hold for this period. Before 2020, the networks' own contribution stayed near zero while employment grew and spread outward. Access rose where new jobs located within reach of existing service, mostly in the middle and outer rings of fast-growing metros, and changed little in the central neighborhoods that already had the most access. Over the decade, the number and location of jobs moved access more than the transit schedule did. The distributional results follow from that geography. The neighborhoods that rely most on transit are central, where job growth added little to an already large set of reachable jobs, and within the same city and distance from the core, jobs moved toward richer neighborhoods. A rise in average access can therefore coexist with little or no gain for the residents who depend on transit. The pandemic adds a second point. In the clean-archive metros, peak job reach from the schedule fell in 2020 and had not recovered by 2025, while agency-reported all-day service returned above its 2014 level (Fig. A.3). Counts of service hours do not show this loss.

The results have three implications for practice. First, agencies and funders that track recovery through service hours, vehicle revenue miles or ridership will overstate the recovery of access to work. In the clean-archive metros, all-day vehicle revenue miles ended the decade about 7% above their 2014 level, while the network's contribution to peak job reach

ended about six log-points below zero. Peak job reach can be computed from an agency's own published schedules, so it can be reported beside service hours. Second, the location of employment is part of transit access policy. In this decade the number and location of jobs changed residents' access to jobs by transit more than changes in service did. For regional plans that set access to jobs as a goal (Section 2), this means the goal depends on where employment grows as well as on transit service, and land-use decisions are part of how it is met. Third, equity analysis should measure access and weight it by the people it concerns. Federally required service equity analyses examine changes in service (Section 2), but the within-city gaps by income, poverty and car ownership that opened over this decade came almost entirely from the movement of jobs (Table 3). Averages over all residents also overstate what transit-dependent households experienced. Weighted by car-free households, the decade's rise falls from 15% to 2.5% (Section 5.5).

The results have several limitations. GTFS records scheduled rather than delivered service, so the panel measures timetabled access rather than the reliability a rider experiences. The panel covers only the morning peak. A constant peak-hour measure tracks relative accessibility across neighborhoods closely (Boisjoly and El-Geneidy, 2016), but off-peak and weekend access matter most for non-standard work schedules, and the post-2020 recovery looks different off-peak (Fig. A.3). Cumulative access counts reachable jobs. It does not account for competition for those jobs, fares, reliability, crowding, safety or transfers, so it measures potential rather than effective access, and the omission of competition matters most for the low-wage workers most dependent on transit (Shen, 1998). LODES records a job at its employer's establishment, so remote work lowers the relevance of physical access for telework-able jobs after 2020 (Dingel and Neiman, 2020). Reweighting the jobs side to work that cannot be done remotely leaves the relocation finding intact. Finally, the archive covers larger, transit-intensive metros best, and where operators entered the archive late, mainly in majority-Black and car-free neighborhoods, the corrected and uncorrected readings differ widely (Figs. 6 and 7).

The analysis is descriptive. It shows where the jobs a rider can reach came from, not whether reaching them changed anyone's employment. The panel provides a longitudinally comparable measure of job access by transit, quarterly and by neighborhood, that causal studies of access and employment can use. Such trend work on archived schedules requires auditing. All but three of the metro-quarters that agency data flagged had passed every internal consistency check (Section 3.3).

Over the past decade, residents of these metros could reach more jobs by transit mainly because employment grew and moved, while transit service added little and then subtracted. The residents who depend on transit gained the least. Whether transit connects households

without a car to work depends on where jobs locate as well as on where and how often transit runs. A policy that tracked only transit service would have missed most of what changed.

A Supporting exhibits

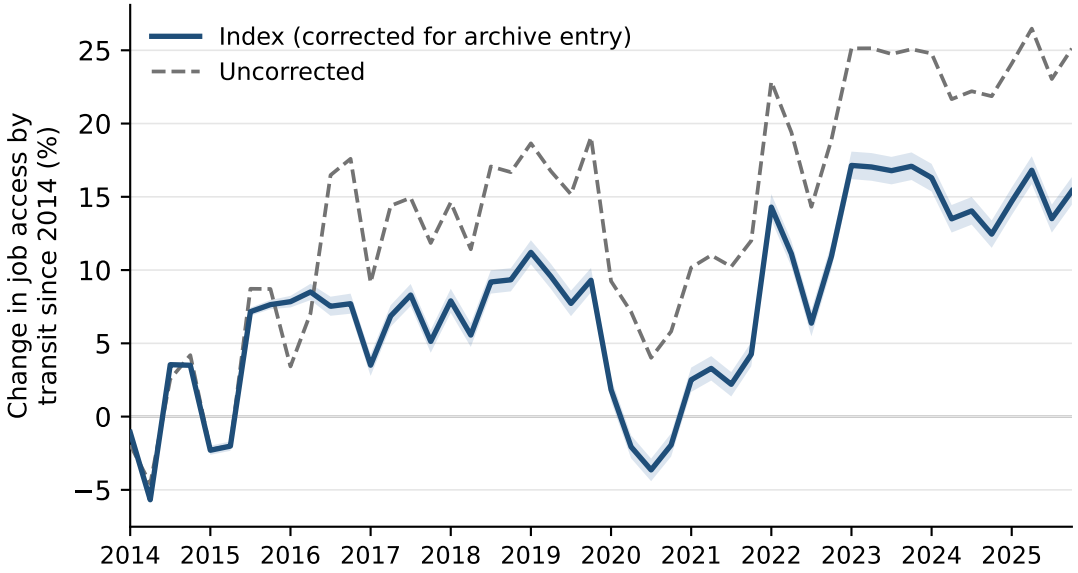

Figures

Figure A.1: The archive-entry correction in one metro: Miami

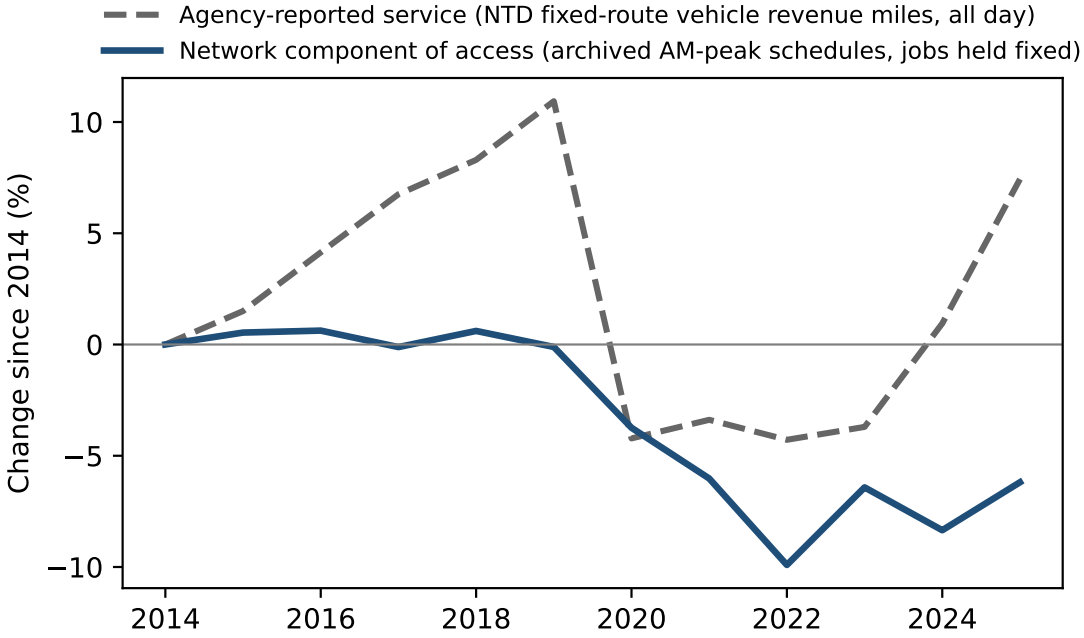

Note: Population-weighted mean job access by transit in Miami: the raw archived series (dashed) and the series with the archive-entry correction applied per block group (solid), percent change against the 2014 annual mean, over the 3,942 block groups present in every covered quarter (the series starts in 2014Q2, and 2015Q2 and 2016Q3–2018Q3 are uncovered; the axis spaces covered quarters evenly). Vertical lines mark changes in Miami's archived operator set; the separations between the two series at those marks are the archive-entry steps the correction removes.

Figure A.2: Change in job access by transit relative to 2014, corrected and uncorrected, 2014–2025

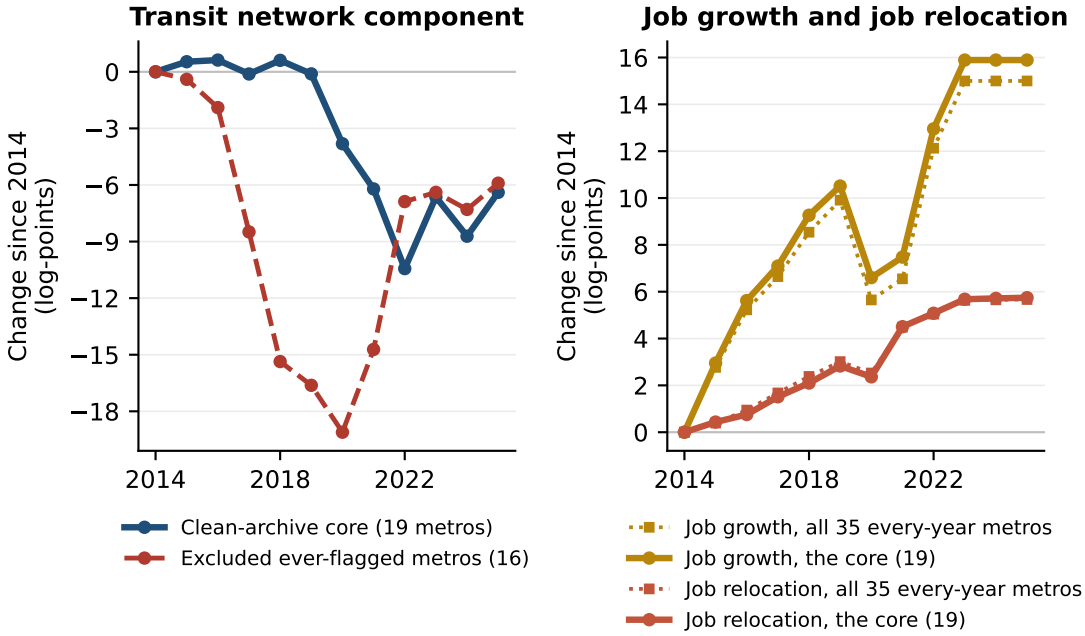

Note: Within-block-group fixed-effects change in jobs reachable within 45 minutes by transit, quarterly, relative to the 2014 average, population-weighted, balanced 52-metro panel outside New York. The solid line is the archive-entry-corrected index of Fig. 4; the dashed line is the uncorrected series. Shading is the 95% block-group-clustered band on the corrected index.

Figure A.3: Transit-network component of access and NTD vehicle revenue miles, 2014–2025

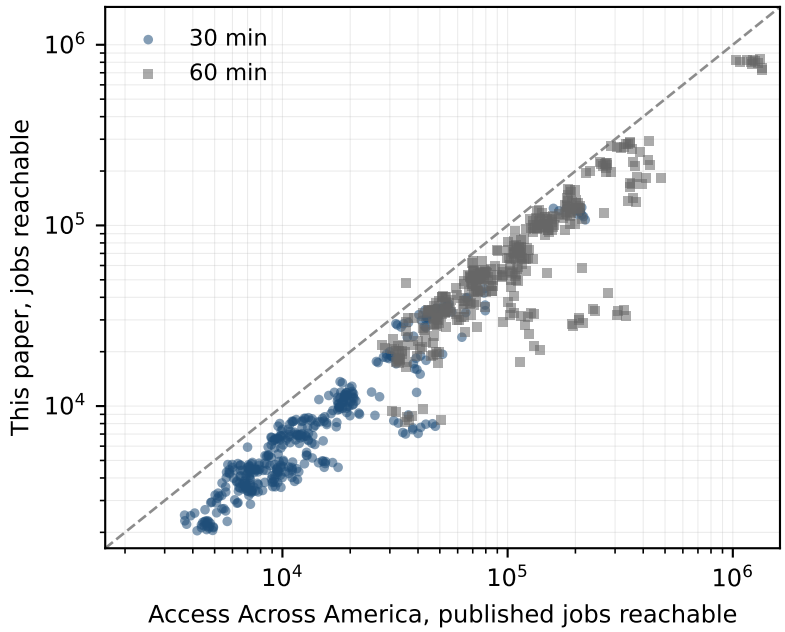

Note: Change since 2014 in agency-reported fixed-route vehicle revenue miles (VRM, from the National Transit Database, the standard measure of service supplied, at all hours; dashed) and in our transit-network component (archived Wednesday-AM-peak schedules, jobs held fixed; solid), pooled over the clean-archive core (19 metros), all with complete 2014–2025 NTD coverage. VRM stands about +11% above its 2014 level by 2019 and about +7% by 2025; the network component is within a point of zero by 2019 and about −6 by 2025. The axis is in percent, the natural unit for the miles comparison; the decomposition exhibits are in log-points (Section 5.1).

Figure A.4: Decomposition component paths by metro archive status

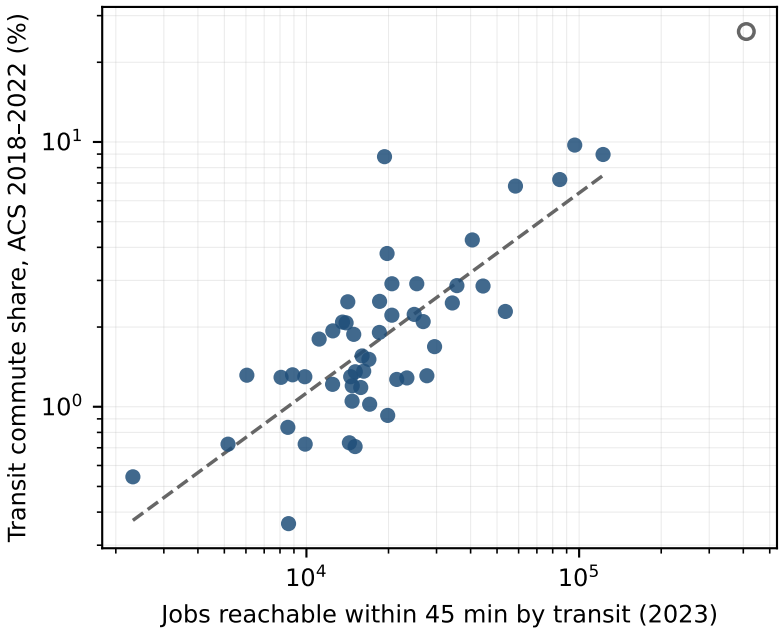

Note: The left panel shows the transit-network component on the clean-archive core (19 metros, solid) and on the 16 every-year metros excluded for flagged quarters (dashed); corrected, within block group, population-weighted, log-points vs the 2014 annual average. The right panel shows the job-growth and job-relocation components on all 35 every-year metros (dotted) and on the core (solid), same construction. Flags mark metro-eras, so an affected metro is excluded whole rather than quarter by quarter (Section 3.3).

Figure A.5: Access levels against published Access Across America values

Note: Our population-weighted metro-year access against the worker-weighted values published in the *Access Across America: Transit* reports (Owen et al., 2016, 2025), at the 30- and 60-minute thresholds, log scales; the dashed line is equality. Across the 390 overlapping metro-years (43 metros, 2014–2024) the correlation in logs is 0.95 at 30 minutes and 0.88 at 60, and our levels sit at a median 0.57 and 0.64 of AAA's (interquartile ranges 0.47–0.64 and 0.54–0.72). The published values cover the urban area and ours the larger cropped metropolitan area, and departure-time protocols and employment vintages also differ; flagged cells are excluded on our side (Section 3.3).

Figure A.6: Metro job access by transit against the ACS transit commute share

Note: Metro job access by transit (2023, flagged cells excluded) against the ACS 2018–2022 transit commute share (table B08301), 51 metros, log scales; the dashed line is the ex–New-York fit (slope ≈ 0.8; $r = 0.77$, or 0.82 including New York, shown hollow).

Tables

Table A.1: The 52 panel metros and quarters present (of 48, 2014–2025)

Metro	Qtrs	Clean	Metro	Qtrs	Clean
Albany, NY	48	47	Milwaukee, WI	48	46
Albuquerque, NM	48	48	Nashville, TN	39	39
Anchorage, AK	46	45	Oklahoma City, OK	38	35

Los Angeles, CA	39	27	Springfield, IL	42	41
Louisville, KY-IN	37	35	Springfield, MA	46	32
Madison, WI	48	48	Stockton, CA	46	46
Miami, FL	38	37	Washington, DC*	43	27

Note: Quarters present (of 48) count flagged cells as present; "Clean" counts the quarters that enter value figures (unflagged). Metros contributing unflagged cells by year: 45 (2014), 48 (2015), 50–52 (2016–2023), 48 (2024), 44 (2025). *Washington, DC: bus operators only, no archived WMATA feed (Section 3.3).

Table A.2: Each exhibit's sample

Exhibit	Sample	Metros	Block groups	Weights
Trajectory (Figs. 4, A.2); group paths (Figs. 5, 6)	The panel	52	85,694	pop.
Levels (Tables 2, A.5)	The panel	52	85,694	pop.
Transit-reliant (Table 4, Fig. 7)	The panel	52	85,694	car-free hh.
Within-city contrasts (Table 3)	Panel, both endpoint windows	45	70,057	pop.
Metro winners (Fig. 8)	Panel, both endpoint windows	45	—	pop.
Decomposition (Fig. 3); NTD check (Fig. A.3)	Clean-archive core	19	28,147	pop.
Map (Fig. 9)	Illustrative metro	1	—	—
New York (Section 6)	New York	1	—	pop.
AAA validation (Fig. A.5)	Panel–AAA overlap	43	—	pop.
Commute-share validation (Fig. A.6)	The panel + New York	51	—	—

Note: The samples are the panel (Section 3.2; balanced 52 metros outside New York) and the clean-archive core (of the panel, the 35 metros observed unflagged in every year, and of those the 19 with no flagged quarter across the decade). The core's members: Albuquerque, Austin, Champaign–Urbana, Charleston, Chicago, Cincinnati, Denver, Kansas City, Madison, Oxnard–Thousand Oaks, Phoenix, Portland, Rochester, Sacramento, San Antonio, Santa Rosa, Seattle, Spokane, and Stockton, holding 33% of the panel's population. Robustness exhibits (thresholds, telework, beginning-of-period attributes) use the panel; Fig. A.4 compares the two.

Table A.3: Archive-integrity flag classes

Class	Detection rule	Cells
Partial outage	an operator present in adjacent quarters is absent from the metro-quarter's archived feed set	73
Thin feed	a metro-quarter's archived schedules carry implausibly little service against the metro's own series	6
Archive scan	level spikes from duplicated feed bundles, and sustained depressions from archive dropout windows, in the full-panel integrity scan	132
NTD divergence	archived-schedule service diverges from agency-reported vehicle revenue miles; corroborated metro-eras (Appendix A)	72

Note: Cells are flagged metro-quarters per class; classes overlap, and some flagged cells fall outside the balanced panel, so the distinct flagged total inside the panel is 136 of 2,330 metro-quarters (5.8%). Flagged cells are excluded from every value figure and count as present for coverage (Section 3.3). Of the 72 NTD-corroborated cells, 69 had passed every internal check.

Table A.4: Representativeness: the 52-metro panel versus all U.S. metros

Metro-level median	Panel (52 metros)	All U.S. metros (392)
Population	1.6M	0.24M
Transit commute share (%)	1.7	0.7
Median household income ($000)	80.5	67.5
Zero-vehicle households (%)	6.0	6.0
Non-Hispanic White (%)	63.1	70.8
Non-Hispanic Black (%)	6.5	6.3
Hispanic (%)	13.4	8.1
Non-Hispanic Asian (%)	4.5	2.0

Note: Medians across metropolitan statistical areas, ACS 2018–2022 (tables B01003, B08301, B19013, B03002, B25044); New York excluded.

Table A.5: Jobs reachable by time budget

Panel A. Outside New York, 2023

Time budget	Transit	Car	Gap
15 min	1.9	164.1	86×
30 min	10.9	780.5	71×
45 min	37.6	1,433.7	38×
60 min	86.9	1,868.2	21×

Panel B. New York, 2014–2025 pooled

Time budget	Transit	Car	Gap
15 min	10.9	505.5	46×
30 min	119.1	2,678.8	22×
45 min	396.4	4,813.6	12×
60 min	800.4	6,445.4	8×

Note: Population-weighted mean jobs reachable within each budget, in thousands, all jobs (C000); "Gap" = car/transit. Panel A is the balanced 52-metro panel, flagged cells excluded; Panel B pools 2014–2025, over which New York's levels are stable (the ex–New-York panel uses 2023 per the levels convention). Car is free-flow, so the gap is an upper bound on the car advantage (Section 3.1).

Table A.6: Correlation among access constructs

	Cumulative	Gravity	Logsum
Cumulative (45 min)	1.00	0.90 (0.90)	0.92 (0.91)
Gravity	0.90 (0.90)	1.00	1.00 (1.00)
Logsum	0.92 (0.91)	1.00 (1.00)	1.00

Note: Pearson correlations of block-group access scores in logs, from the routed 2019Q4 travel-time matrices (a dense, pre-pandemic quarter), n = 85,694 block groups, 52 metros outside New York; pooled, with the median within-metro correlation in parentheses. Constructs: the paper's cumulative measure (jobs reachable within 45 minutes); a gravity measure with negative-exponential impedance, half-life 45 minutes ($\sum_j \text{jobs}_j \, e^{-(\ln 2/45)\, t_{ij}}$); and a destination-choice logsum ($\ln \sum_j \text{jobs}_j \, e^{-t_{ij}/45}$, a 45-minute decay constant, equivalent to a half-life of about 31 minutes). The two smooth-impedance parameters are deliberately distinct (identical impedance would make the logsum the log of the gravity measure by construction); both are scaled to the paper's 45-minute budget, following the common-budget logic of Santana Palacios and El-Geneidy (2022).

Table A.7: Main statistics under block-group and metro clustering

Statistic	Estimate	BG-clustered	Metro-spec est.	Metro-clustered
Trajectory, 2025 (corrected)	+14.1	[+13.3, +14.8]	+14.9	[+6.1, +23.8]
at 2019Q4	+8.9	[+8.1, +9.7]	+5.2	[−9.2, +19.6]
Decomposition: job growth	+15.9	—	+15.0	[+11.8, +18.2]
job relocation	+5.7	[+5.1, +6.4]	+5.3	[+2.8, +7.8]
transit network	−6.4	[−7.0, −5.9]	−4.9	[−17.6, +7.9]
Growth, richest quartile	+30.9	[+28.8, +33.0]	+30.9	[+17.6, +45.7]
Growth, majority-Black (45 min)	−9.0	[−11.4, −6.5]	−9.0	[−18.2, +1.2]
Within-city: poorest−richest	−20.7	[−22.1, −19.2]	−20.7	[−26.8, −14.5]
majority-Black−White	−10.7	[−13.0, −8.3]	−9.4	[−19.4, +0.6]

Note: Bracketed ranges are 95% confidence intervals. Trajectory and group growth: archive-entry-corrected within-BG FE (trajectory in log-points relative to the 2014 base, group growth in percent). Decomposition: 2025 vs. the 2014 average, log-points; job growth is an accounting identity at the block-group level, so only its metro-level variation is reported. Within-city contrasts: metro × 5-km cells absorbed, log-points. Point estimates are those reported in Sections 5.1–5.4; the metro-clustered specification uses the 2014Q1 base on the full balanced panel, and its own point estimates are shown beside its intervals. The two sets of points differ through the base, correction, and (for the decomposition rows) sample treatment without altering the metro-level significance. Metro clustering: ≈ 52 clusters (45 for the within-city rows).

Table A.8: Reconciliation of the trajectory and decomposition estimands

	2025 endpoint
(1) Reported trajectory (52 metros, quarterly, fixed-effects correction)	+14.1
(2) Same estimator on the every-year subset	+14.7
(3) Same estimator on its never-flagged metros	+16.1
(4) Decomposition observed (annual, jumps removed, same sample)	+15.2
Coverage sample step, (1)→(2)	+0.6
Archive-quality sample step, (2)→(3)	+1.4
Construction step, (3)→(4)	−0.9

Note: The trajectory estimand and the decomposition estimand, reconciled on a common basis (Section 5.1), 2025 vs. 2014 in log-points: the two sample steps are the every-year restriction and then the clean-archive (never-flagged) restriction; the construction step compares annual endpoint means with each block group's entry jumps removed against the quarterly fixed-effects correction.
